1. Abstract

RIKEN BNL Research Center (RBRC) Experimental Group studies the strong interactions (QCD) using RHIC accelerator at Brookhaven National Laboratory, the world first heavy ion collider and polarized $p + p$ collider. We have three major activities: Spin Physics at RHIC, Heavy ion physics at RHIC, and detector upgrades of PHENIX experiment at RHIC.

We study the spin structure of the proton using the polarized proton-proton collisions at RHIC. This program has been promoted by RIKEN’s leadership. The first focus of the research is to measure the gluon spin contribution to the proton spin. Recent results from PHENIX $p^0$ measurement and STAR jet measurement has shown that gluons in the proton carry about 30% of the proton spin. This is a major milestone of RHIC spin program. The second goal of the spin program is to measure the polarization of anti-quarks in the proton using $W \rightarrow e$ and $W \rightarrow \mu$ decays. The results of $W \rightarrow e$ measurement was published in 2016. The final results of $W \rightarrow \mu$ was published in 2018.

The aim of Heavy ion physics at RHIC is to re-create Quark Gluon Plasma (QGP), the state of Universe just after the Big Bang. Two important discoveries, jet quenching effect and strong elliptic flows, have established that new state of dense matter is indeed produced in heavy ion collisions at RHIC. We are now studying the property of the matter. Recently, we have measured direct photons in Au + Au collisions for $1 < p_T < 3$ GeV/$c$, where thermal radiation from hot QGP is expected to dominate. The comparison between the data and theory calculations indicates that the initial temperature of 300 MeV to 600 MeV is achieved. These values are well above the transition temperature to QGP, which is calculated to be approximately 160 MeV by lattice QCD calculations.

We had major roles in detector upgrades of PHENIX experiment, namely, the silicon vertex tracker (VTX) and muon trigger upgrades. Both of the upgrade is now complete. The VTX is the main device to measure heavy quark (charm and bottom) production and the muon trigger is essential for $W \rightarrow \mu$ measurement. The results from the first run with VTX detector in 2011 was published. The results show that electrons from bottom quark decay is strongly suppressed at high $p_T$, but the suppression is weaker than that of charm decay electron for $3 < p_T < 4$ GeV/$c$. We have recorded 10 times as much Au + Au collisions data in each of the 2014 run and 2016 run. The large dataset will produce definitive results on heavy quark production at RHIC.

PHENIX completed its data taking in 2016. We are now working on R&D of intermediate silicon tracker INTT for sPHENIX, a new experiment at RHIC that will be installed in the PHENIX IR.

2. Major Research Subjects

(1) Experimental Studies of the Spin Structure of the Nucleon
(2) Study of Quark-Gluon Plasma at RHIC
(3) sPHENIX INTT detector

3. Summary of Research Activity

We study the strong interactions (QCD) using the RHIC accelerator at Brookhaven National Laboratory, the world first heavy ion collider and polarized $p + p$ collider. We have three major activities: Spin Physics at RHIC, Heavy ion physics at RHIC, and detector upgrades of PHENIX experiment. From 2016, Y. Akiba (Experimental Group Leader) is the Spokesperson of PHENIX experiment.

(1) Experimental study of spin structure of proton using RHIC polarized proton collider

How is the spin of proton formed with 3 quarks and gluons? This is a very fundamental question in Quantum Chromodynamics (QCD), the theory of the strong nuclear forces. The RHIC Spin Project has been established as an international collaboration between RIKEN and Brookhaven National Laboratory (BNL) to solve this problem by colliding two polarized protons for the first time in history. This project also has extended the physics capabilities of RHIC.

The first goal of the Spin Physics program at RHIC is to determine the gluon contribution to proton spin. It is known that the spin of quark accounts for only 25% of proton spin. The remaining 75% should be carried either by the spin of gluons or the orbital angular momentum of quarks and gluons. One of the main goals of the RHIC spin program has been to determine the gluon spin contribution. Before the start of RHIC, there was little experimental constraint on the gluon polarization, $\Delta G$.

PHENIX measures the double helicity asymmetry ($A_{LL}$) of $p^0$ production to determine the gluon polarization. Our most recent publication of $p^0 A_{LL}$ measurement at 510 GeV shows non-zero value of $A_{LL}$, indicating that gluons in the proton is polarized. Global analysis shows that approximately 30% of proton spin is carried by gluons.

Figure 1 and Fig. 2 shows most recent spin physics measurement with PHENIX from our group. Figure 1 show the $A_{LL}$ of charged pions in polarized $p + p$ collisions at $\sqrt{s} = 510$ GeV and Fig. 2 shows $A_{N}(p_T)$ of very forward neutron. These results are published in Physical Review D.

Members of our group also participate in RHICf experiment, a small experiment at RHIC to measure particle production and single spin asymmetry of particles produced at very forward direction. Figure 3 shows $A_N(x_F)$ of very forward $p^0$ measured by RHICf compared with other experiments, published in Physical Review Letters. This is the first published results of RHICf experiment.

(2) Experimental study of Quark-Gluon Plasma using RHIC heavy-ion collider

The goal of high energy heavy ion physics at RHIC is study of QCD in extreme conditions i.e. at very high temperature and at
Before the start of RHIC, there was little experimental constraint on the gluon polarization, momentum of quarks and gluons. One of the main goals of the RHIC spin program has been to determine the gluon spin contribution. Of quark accounts for only 25% of proton spin. The remaining 75% should be carried either by the spin of gluons or the orbital angular history. This project also has extended the physics capabilities of RHIC.

RIKEN and Brookhaven National Laboratory (BNL) to solve this problem by colliding two polarized protons for the first time in the proton using $(1)$ Experimental study of spin structure of proton using RHIC polarized proton collider and the muon trigger is essential for $W$ the transition temperature to QGP, which is calculated to be approximately 160 MeV by lattice QCD calculations. The data and theory calculations indicates that the initial temperature of 300 MeV to 600 MeV is achieved. These values are well above compared with other experiments, published in Physical Review Letters. This is the first published results of RHICf experiment. This is a major milestone of RHIC spin program. The second goal of the spin program is to measure the polarization of anti-quarks from PHENIX Physics at RHIC, Heavy ion physics at RHIC, and detector upgrades of PHENIX experiment at RHIC.

very high energy density. Experimental results from RHIC have established that dense partonic matter is formed in Au + Au collisions at RHIC. The matter is very dense and opaque, and it has almost no viscosity and behaves like a perfect fluid. These conclusions are primarily based on the following two discoveries:

- Strong suppression of high transverse momentum hadrons in central Au + Au collisions (jet quenching)
- Strong elliptic flow

These results are summarized in PHENIX White paper, which has more than 3000 citations to date. The focus of the research in heavy ion physics at RHIC is now to investigate the properties of the matter. RBRC have played the leading roles in some of the most
important results from PHENIX in the study of the matter properties. These include (1) measurements of heavy quark production from the single electrons from heavy flavor decay (2) measurements of \( J/\Psi \) production (3) measurements of di-electron continuum and (4) measurements of direct photons.

Our most important result is the measurement of direct photons for \( 1 < p_T < 5 \text{ GeV}/c \) in \( p + p \) and \( \text{Au} + \text{Au} \) through their internal conversion to \( e^+e^- \) pairs. If the dense partonic matter formed at RHIC is thermalized, it should emit thermal photons. Observation of thermal photon is direct evidence of early thermalization, and we can determine the initial temperature of the matter. It is predicted that thermal photons from QGP phase is the dominant source of direct photons for \( 1 < p_T < 3 \text{ GeV}/c \) at the RHIC energy. We measured the direct photon in this \( p_T \) region from measurements of quasi-real virtual photons that decays into low-mass \( e^+e^- \) pairs. Strong enhancement of direct photon yield in \( \text{Au} + \text{Au} \) over the scaled \( p + p \) data has been observed. Several hydrodynamical models can reproduce the central \( \text{Au} + \text{A} \) data within a factor of two. These models assume formation of a hot system with initial temperature of \( T_{\text{init}} = 300 \text{ MeV} \) to \( 600 \text{ MeV} \). This is the first measurement of initial temperature of quark gluon plasma formed at RHIC. Y. Akiba received 2011 Nishina memorial Prize mainly based on this work.

PHENIX experiment recently measured the flow in small collision systems (\( p + \text{Au}, d + \text{Au}, \) and \( ^3\text{He} + \text{Au} \), and observed strong flow in all of these systems. Theoretical models that assume formation of small QGP droplets best describe the data. These results are published in Nature Physics in 2019.

(3) sPHENIX INTT detector

The group had major roles in several PHENIX detector upgrades, namely, the silicon vertex tracker (VTX) and muon trigger upgrades. VTX is a high precision charged particle tracker made of 4 layers of silicon detectors. It is jointly funded by RIKEN and the US DOE. The inner two layers are silicon pixel detectors and the outer two layers are silicon strip detectors. Y. Akiba is the project manager and A. Deshpande is the strip system manager. The VTX detector was completed in November 2010 and subsequently installed in PHENIX. The detector started taking data in the 2011 run. With the new detector, we measure heavy quark (charm and bottom) production in \( p + p, \text{A} + \text{A} \) collisions to study the properties of quark-gluon plasma. The final result of the 2011 run was published. The result show that single electrons from bottom quark decay is suppressed, but not as strong as that from charm decay in low \( p_T \) region (\( 3 < p_T < 4 \text{ GeV}/c \)). This is the first measurement of suppression of bottom decay electrons at RHIC and the first observation that bottom suppression is smaller than charm. We have recorded 10 times as much \( \text{Au} + \text{Au} \) collisions data in each of the 2014 run and 2016 run. The large dataset will produce definitive results on heavy quark production at RHIC. A preliminary results on the elliptic flow strength \( v_2 \) of \( b \rightarrow e \) and \( c \rightarrow e \) has been presented in Quark Matter 2018 conference. The results of bottom/charm ratios in \( p + p \) collisions at 200 GeV from the 2015 run was published (Phys. Rev. D 99 092003 (2019)). A paper reporting measurements of the nuclear suppression factor \( R_{AA} \) of charm and bottom in \( \text{Au} + \text{Au} \) collisions from the 2014 data is in preparation.

PHENIX completed its data taking in 2016. We are now working on construction of intermediate silicon tracker INTT for sPHENIX, a new experiment at RHIC that will start taking data in 2023. Figure 4 shows snapshot of INTT construction work. INTT consists of 56 ladders of silicon detector. So far approximately 30 ladders are produced. INTT will be completed in JFY2021.
